METHODOLOGY

Equivalent layer technique for gravity data processing

Let d_i^o be the observed gravity data at the point (x_i, y_i, z_i) , $i = 1, \dots, N$, of a local Cartesian system with x axis pointing to North, the y axis pointing to East and the z axis pointing

downward. We consider that the gravity data are properly processed so that they represent the difference between the observed gravity (corrected from non-gravitational effects due to the vehicle motion) and the normal gravity, at the same point. This quantity is called *gravity disturbance* (Hofmann-Wellenhof and Moritz, 2005). Several authors have discussed the differences between the gravity anomaly and the gravity disturbance, as well as proposed that the second is more appropriated for geophysical applications. A detailed discussion about this theoretical topic is beyond the scope of our work and we refer the reader to Li and Götze (2001); Fairhead et al. (2003); Hackney and Featherstone (2003); Hinze et al. (2005) and Vajda et al. (2006, 2007, 2008), for example.

In a local coordinate system, the gravity disturbance can be considered as the z - component (or vertical component) of the gravitational attraction exerted by gravity sources. As a consequence, it can be approximated by a linear combination of ...

$$\delta g(x_i, y_i, z_i) = \sum_{j=1}^N p_j a_{ij} , \quad (1)$$

$$a_{ij} = \frac{G (z_0 - z_i) 10^{-5}}{[(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_0)^2]^{\frac{3}{2}}} . \quad (2)$$

$$\mathbf{d}(\mathbf{p}) = \mathbf{A} \mathbf{p} , \quad (3)$$

The elements a_{ij} (equation 2) forming the matrix \mathbf{A} (equation 3) are defined in terms of the coordinates x_i , y_i , x_j and y_j , which are associated with the observed data and the equivalent sources. Based on this, we designate these coordinates as *matrix coordinates* and the indices i and j as *matrix indices*.

$$\Psi(\mathbf{p}) = \|\mathbf{d}^o - \mathbf{d}(\mathbf{p})\|_2^2 + \mu \|\mathbf{p}\|_2^2, \quad (4)$$

$$\hat{\mathbf{p}} = \left(\mathbf{A}^\top \mathbf{A} + \mu \mathbf{I} \right)^{-1} \mathbf{A}^\top \mathbf{d}^o. \quad (5)$$

Structure of matrix \mathbf{A} for regular grids

Consider that the observed data are located on an $N_x \times N_y$ regular grid of points regularly spaced from Δx and Δy along the x and y directions, respectively, on a horizontal plane defined by the constant vertical coordinate $z_1 < z_0$. As a consequence, a given pair of matrix coordinates (x_i, y_i) , defined by the matrix index i , $i = 1, \dots, N = N_x N_y$, is equivalent to a pair of coordinates (x_k, y_l) given by:

$$x_i \equiv x_k = x_1 + [k(i) - 1] \Delta x, \quad (6)$$

and

$$y_i \equiv y_l = y_1 + [l(i) - 1] \Delta y, \quad (7)$$

where $k(i)$ and $l(i)$ are integer functions of the matrix index i . These equations can also be used to define the horizontal coordinates x_j and y_j associated with the j -th equivalent source, $j = 1, \dots, N = N_x N_y$. In this case, the integer functions are evaluated by using the index j instead of i . For convenience, we designate x_k and y_l as *grid coordinates* and the indices k and l , defined by the integer functions, as *grid indices*.

The integer functions assume different forms depending on the orientation of the regular grid of data. Consider the case in which the grid is oriented along the x -axis (Figure 1a). For convenience, we designate these grids as *x-oriented grids*. For them, we have the following

integer functions:

$$i(k, l) = (l - 1) N_x + k \quad , \quad (8)$$

$$l(i) = \left\lceil \frac{i}{N_x} \right\rceil \quad (9)$$

and

$$k(i) = i - \left\lceil \frac{i}{N_x} \right\rceil N_x + N_x \quad , \quad (10)$$

where $\lceil \cdot \rceil$ denotes the ceiling function (Graham et al., 1994, p. 67). These integer functions are defined in terms of the matrix index i , but they can be defined in the same way by using the index j instead of i . Figure 1a illustrates an x -oriented grid defined by $N_x = 4$ and $N_y = 3$. In this example, the matrix coordinates x_7 and y_7 , defined by the matrix index $i = 7$ (or $j = 7$), are equivalent to the grid coordinates x_3 and y_2 , which are defined by the grid indices $k = 3$ and $l = 2$, respectively. These indices are computed with equations 9 and 10, by using the matrix index $i = 7$ (or $j = 7$).

Now, consider the case in which the regular grid of data is oriented along the y -axis (Figure 1b). For convenience, we call them *y-oriented grids*. Similarly to x -oriented grids, we have the following integer functions associated with y -oriented grids:

$$i(k, l) = (k - 1) N_y + l \quad , \quad (11)$$

$$k(i) = \left\lceil \frac{i}{N_y} \right\rceil \quad (12)$$

and

$$l(i) = i - \left\lceil \frac{i}{N_y} \right\rceil N_y + N_y \quad . \quad (13)$$

Figure 1b illustrates an y -oriented grid defined by $N_x = 4$ and $N_y = 3$. In this example, the matrix coordinates x_7 and y_7 , defined by the matrix index $i = 7$ (or $j = 7$), are equivalent to the grid coordinates x_3 and y_1 , which are defined by the grid indices $k = 3$ and $l = 1$,

respectively. Differently from the example shown in Figure 1a, the grid indices of the present example are computed with equations 12 and 13, by using the matrix index $i = 7$ (or $j = 7$).

The element a_{ij} (equation 2) can be rewritten by using equations 6 and 7 to define the matrix coordinates x_i , y_i , x_j and y_j . In this way, they are defined in terms of the integer function as follows:

$$a_{ij} = \frac{G \Delta z 10^{-5}}{\left[(\Delta k_{ij} \Delta x)^2 + (\Delta l_{ij} \Delta y)^2 + (\Delta z)^2 \right]^{\frac{3}{2}}}, \quad (14)$$

where $\Delta z = z_0 - z_1$, $\Delta k_{ij} = k(i) - k(j)$ (equations 10 and 12) and $\Delta l_{ij} = l(i) - l(j)$ (equations 9 and 13). The structure of matrix \mathbf{A} (equation 3), for the case in which its elements are given by a_{ij} (equation 14), is defined by the coefficients Δk_{ij} and Δl_{ij} .

For x -oriented grids, the coefficients Δk_{ij} and Δl_{ij} are computed by using equations 10 and 9, respectively. In this case, \mathbf{A} (equation 3) is a Block-Toeplitz Toeplitz-Block (BTTB) matrix (Chan and Jin, 2007, p. 67) composed of $N_y \times N_y$ blocks, where each block is formed by $N_x \times N_x$ elements. In this kind of matrix, blocks lying at the same diagonal are equal to each other and they are themselves Toeplitz matrices. We follow the common notation found in the literature to represent blocks lying at the same diagonal as \mathbf{A}_m , where m is an index that we conveniently call *block index*. The block indices m associated with the blocks \mathbf{A}_m lying at, above and below the main diagonal of \mathbf{A} assume the values $m = 0$, $m > 0$ and $m < 0$, respectively. Those above the main diagonal have m varying from 1, close to the main diagonal, to $N_y - 1$, at the upper right corner of \mathbf{A} . On the other hand, those below the main diagonal have m varying from -1 , close to the main diagonal, to $-N_y + 1$, at the bottom left corner of \mathbf{A} . For y -oriented grids, the coefficients Δk_{ij} and Δl_{ij} are computed by using equations 12 and 13, respectively. In this case, \mathbf{A} (equation 3) is a BTTB matrix composed of $N_x \times N_x$ blocks, where each block is formed by $N_y \times N_y$ elements. The block

index m associated with y -oriented grids vary from $-N_x + 1$, at the bottom left, to $N_x - 1$, at the upper right corner of \mathbf{A} .

Consider a given block \mathbf{A}_m of the matrix \mathbf{A} (equation 3) defined by elements a_{ij} (equation 14) that are computed in an x -oriented grid. In this case, the coefficients Δk_{ij} (equation 10) associated with the elements ij within \mathbf{A}_m form a Skew-Symmetric Toeplitz matrix $\Delta \mathbf{K}_m$ (Golub and Loan, 2013, p. 161). The first column of this matrix is formed by the integer elements $0, 1, \dots, N_x - 1$. On the other hand, all the coefficients Δl_{ij} (equation 9) that define the elements ij within \mathbf{A}_m have the same value $-m$. As a consequence, they form a matrix $\Delta \mathbf{L}_m = -m \mathbf{1}$, where $\mathbf{1}$ is a matrix with all elements equal to 1. This well-defined pattern of matrices $\Delta \mathbf{K}_m$ and $\Delta \mathbf{L}_m$ can be easily verified by computing the coefficients Δk_{ij} (equation 10) and Δl_{ij} (equation 9) for all matrix indices i and j . By using the x -oriented grid shown in Figure 1a, the matrices $\Delta \mathbf{K}_m$ and $\Delta \mathbf{L}_m$ defined by using, for example, the block index $m = 1$, are given by:

$$\Delta \mathbf{K}_1 = \begin{bmatrix} 0 & -1 & -2 & -3 \\ 1 & 0 & -1 & -2 \\ 2 & 1 & 0 & -1 \\ 3 & 2 & 1 & 0 \end{bmatrix} \quad (15)$$

and

$$\Delta \mathbf{L}_1 = \begin{bmatrix} -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & -1 \end{bmatrix} . \quad (16)$$

Consider now a given block \mathbf{A}_m of the matrix \mathbf{A} (equation 3) defined by elements a_{ij} (equation 14) that are computed in an y -oriented grid. In this case, the coefficients Δk_{ij}

(equation 12) associated with the elements ij within \mathbf{A}_m form a matrix $\Delta\mathbf{K}_m = -m\mathbf{1}$. On the other hand, the matrix $\Delta\mathbf{L}_m$ formed by the coefficients Δl_{ij} (equation 13) that define the elements ij within \mathbf{A}_m is a Skew-Symmetric Toeplitz matrix. The first column of this matrix is formed by the integer elements $0, 1, \dots, N_y - 1$. This well-defined pattern of matrices $\Delta\mathbf{K}_m$ and $\Delta\mathbf{L}_m$ can also be verified by computing the coefficients Δk_{ij} (equation 12) and Δl_{ij} (equation 13) for all matrix indices i and j . To illustrate these matrices, we compute them by using the y -oriented grid shown in Figure 1b and a block index $m = 1$. The results are given by:

$$\Delta\mathbf{K}_1 = \begin{bmatrix} -1 & -1 & -1 \\ -1 & -1 & -1 \\ -1 & -1 & -1 \end{bmatrix} \quad (17)$$

and

$$\Delta\mathbf{L}_1 = \begin{bmatrix} 0 & -1 & -2 \\ 1 & 0 & -1 \\ 2 & 1 & 0 \end{bmatrix} . \quad (18)$$

From these examples (equations 15, 16, 17 and 18), we conclude that, in both cases (x - and y -oriented grids), the blocks \mathbf{A}_m above the main diagonal (with block index $m > 0$) are equal to those below the main diagonal (with block index $m < 0$), i. e., $\mathbf{A}_m = \mathbf{A}_{-m}$. Besides, we can see that each block \mathbf{A}_m is a symmetric Toeplitz matrix. These symmetries come from the fact that the coefficients Δk_{ij} (equations 10 and 12) and Δl_{ij} (equations 9 and 13) are squared at the denominator of a_{ij} (equation 14).

Computational performance

In a normal procedure of the fast equivalent layer proposed by Siqueira et al. (2017), at each iteration a full matrix \mathbf{A} (equation 3) is multiplied by the estimated mass distribution parameter vector $\hat{\mathbf{p}}^k$ producing the predicted gravity data $\mathbf{d}(\mathbf{p})$ iteratively. As pointed in Siqueira et al. (2017) the number of flops (floating-point operations) necessary to estimate the N -dimensional parameter vector inside the iteration loop is:

$$f_0 = N^{it}(3N + 2N^2), \quad (19)$$

where N^{it} is the number of iterations. From equation 19 it is clear that the matrix-vector product ($2N^2$) accounts for most of the computational complexity in this method.

It is well known that FFT takes $N \log_2(N)$ flops (?). Computing the eigenvalues of the BCCB matrix ($4N \times 4N$) and applying 2D-FFT on the parameter vector (equation ??), takes $4N \log(4N)$ each. The point-multiplication takes $4N$. As it is necessary to compute the inverse FFT another two $4N \log(4N)$ must be taken in account. However, the sensibility matrix does not change during the process, thus, the eigenvalues of BCCB must be calculated only once, outside of the iteration. This lead us to a flops count in our method of:

$$f_1 = 4N \log(4N) + N^{it}(7N + 8N \log(4N)). \quad (20)$$

Another major improvement of this methodology is the exoneration of calculating the full sensibility matrix \mathbf{A} (equation 3). Each element needs 12 flops (equation 2), totalizing $12N^2$ flops for the full matrix. Calculating only the first row of the BTTB matrix $12N$ flops

is required. Thus, the full flops count of the method presented by Siqueira et al. (2017):

$$f_s = 12N^2 + N^{it}(3N + 2N^2), \quad (21)$$

it is decreased in our method to:

$$f_f = 12N + 4N \log(4N) + N^{it}(7N + 8N \log(4N)). \quad (22)$$

Figure 1 shows the floating points to estimate the parameter vector using the fast equivalent layer with the method of Siqueira et al. (2017) (equation 19) and our approach (equation 20) versus the number of observation points varyig from $N = 5000$ to $N = 1000000$ with 50 iterations. The number of operations is drastically decreased.

Table 1 shows the system memory RAM usage needed to store the full sensibility matrix, the BTTB first row and the BCCB eigenvalues (8 times the BTTB first row). The quantities were computed for different numbers of data (N) with the same corresponding number of equivalent sources (N). Table 1 considers that each element of the matrix is a double-precision number, which requires 8 bytes of storage, except for the BCCB complex eigenvalues, which requires 16 bytes per element. Notice that 1,000.000 observation points requires nearly 7.6 Terabytes of memory RAM to store the whole sensibility matrix of the equivalent layer.

Using a PC with a Intel Core i7 4790@3.6GHz processor and 16 Gb of memory RAM, Figure 2 compares the running time of the Siqueira et al. (2017) method with the one of our work, considering a constant number of iterations equal to 50. Clearly, the major advantage of our approach is its computational efficiency that allows a rapid calculation of the gravity

forward modeling with number of observations greater than 10,000. Because of the RAM available in this system, we could not perform this comparison with more observations. Therefore, the number of observation is limited to 22,500. Disregarding the limitation of 16 Gb of RAM, Figure 3 shows the running time of our method with 50 iterations and with the number of observations up to 25 millions. Our method requires 26 : 8 seconds to run one million of observations, whereas Siqueira et al. (2017) method took 48 : 3 seconds to run 22,500 observations

SYNTHETIC TESTS

In this section, we investigate the effectiveness of using the properties of BTTB and BCCB matrices (equation ??) to solve, at each iteration, the forward modeling (the matrix-vector product $\mathbf{A}\hat{\mathbf{p}}^k$) required in the fast equivalent layer proposed by Siqueira et al. (2017). We simulated three sources whose horizontal projections are shown in Figure 4 as black lines. These sources are two vertical prisms with density contrasts of $0.35g/cm^3$ (upper-left prism) and $0.4g/cm^3$ (upper-right prism) and a sphere with radius of 1,000 m with density contrast of $-0.5g/cm^3$. Figure 4 shows the vertical component of gravity field generated by these sources contaminated with additive pseudorandom Gaussian noise with zero mean and standard deviation of 0.01486 mGal.

The advantage of using the structures of BTTB and BCCB matrices to compute forward modeling in the fast equivalent layer proposed by Siqueira et al. (2017) is grounded on the use of regular grids of data and equivalent sources. Hence, we created 10,000 observation points regularly spaced in a grid of 100×100 at 100 m height. We also set a grid of equivalent point masses, each one directly beneath each observation points, located at 300 m deep. Figures 5a and 6a show the fitted gravity data obtained, respectively, by the fast equivalent

layer using Siqueira et al. (2017) method and by our modified form of this method that computes the forward modeling using equation ???. The corresponding residuals (Figures 5b and 6b), defined as the difference between the observed (Figure 4) and fitted gravity data (Figures 5a and 6a), show means close to zero and standard deviations of 0.0144 mGal. Therefore, Figures 5 and 6 show that Siqueira et al. (2017) method and our modified version of this method produced virtually the same results. This excellent agreement is confirmed in Figures 7 and 8 which shows that there are virtually no differences, respectively, in the fitted data presented in Figures 5b and 6b and in the estimated mass distributions within the equivalent layers (not shown) yielded by both Siqueira et al. (2017) method and our modification of this method. These results (7 and 8) show that computing the matrix-vector product $(\mathbf{A}\hat{\mathbf{p}}^k)$, required in the forward modeling, by means of embedding the BTTB matrix into a BCCB matrix (equation ??) yields practically the same result as the one produced by computing this matrix-vector product with a full matrix \mathbf{A} .

We perform two forms of processing the gravity data (Figure 4) through the equivalent layer technique: the upward (Figure 9) and the downward (Figure 10) continuations. The upward height is 300m and the downward is at 50m. Either in the upward continuation (Figure 9) or in the downward continuation (Figure 10), the continued gravity data using the fast equivalent layer proposed by Siqueira et al. (2017) (Figures 9a and 10a) are in close agreement with those produced by our modification of Siqueira et al. (2017) method (Figures 9b and 10b). The residuals (Figures 9c and 10c) quantify this agreement since their means and standard deviations are close to zero in both continued gravity data using both methods. All the continued gravity data shown here (Figures 9 and 10) agree with the true ones (not shown). The most striking feature of these upward or the downward continuations concerns the total computation time. The computation time spent by our

method is approximately 1500 times faster than Siqueira et al. (2017) method.

REAL DATA TEST

Test with real data are conducted with the gravity data from Carajás, north of Brazil, were provided by the Geological Survey of Brazil (CPRM). The real aerogravimetric data were collected in 113 flight lines along northsouth direction with flight line spacing of 3 km and tie lines along eastwest direction at 12 km.

This airborne gravity survey was divided in two different areas, collected in different times, having samples spacing of 7.65 m and 15.21 m, totalizing 4,353,428 observation points. The height of the flight was fixed at 900 m. The gravity data (Figure 11) were gridded into a regularly spaced dataset of 250,000 observation points (500×500) with a grid spacing of 716.9311 km north-south and 781.7387 km east-west.

To apply our modification of the fast equivalent layer method (Siqueira et al., 2017) that computes the forward modeling using the properties of BTTB and BCCB matrices (equation ??), we set an equivalent layer at 300 m deep. Figure 12a shows the fitted gravity data after with 50 iterations by applying our method approach. The residuals (Figure 12b), defined as the difference between the observed (Figure 11) and the predicted (Figure 12a) data, show an acceptable data fitting because they have a mean close to zero (0.000292 mGal) and a small standard deviation of 0.105 mGal which corresponds to approximately 0.1 % of the amplitude of the gravity data.

These small residuals indicate that our method yielded an estimated mass distribution (not shown) that can be used in the data processing. We perform upward-continuation of the real gravity data (Figure 11) at a constant height of 5000 m over the real data.

The upward-continued gravity data (Figure 13) seem a reasonable processing because of the attenuation of the short-wave lengths. By using our approach, the processing of the 250,000 observations was extremely fast and took 0.216 seconds.

CONCLUSIONS

By exploring the properties related to Block-Toeplitz Toeplitz-block (BTTB) and Block-Circulant Circulant-Block (BCCB) matrices in the gravity data processing, we have proposed a new efficient approach for calculating the gravity-data forward modeling required in the iterative fast equivalent-layer technique grounded on excess mass constraint that does not demand the solution of linear systems. Its efficiency is grounded on the use of regular grids of observations and equivalent sources (point masses). Our algorithm greatly reduces the number of flops necessary to estimate a 2D mass distribution within the equivalent layer that fits the observed gravity data. For example, when processing one million observations the number of flops is reduced in 104 times. Traditionally, such amount of data impractically requires 7.6 Terabytes of RAM memory to handle the full sensibility matrix. Rather, in our method, this matrix takes 61,035 Megabytes of RAM memory only.

Our method takes advantage of the symmetric BTTB system that arises when processing a harmonic function as the vertical component of gravity, that depends on the inverse of distance between the observation and the point mass over the equivalent layer. Symmetric BTTB matrices can be stored by its only first row and can be embedded into a symmetric BCCB matrix, which in turn also only needs its first row.

Using the fast Fourier transform it is possible to calculate the eigenvalues of BCCB matrices which can be used to compute a matrix-vector product (gravity-data forward

modeling) in a very low computational cost. The time needed to process medium-sized grids of observation, for example 22,500 points, is reduced in 102 times. We have successfully applied the proposed method to upward (or downward) synthetic gravity data. Testing on field data from the Carajás Province, north of Brazil, confirms the potential of our approach in upward-continuing gravity data with 250,000 observations in about 0.2 seconds. Our method allows, in future research, applying the equivalent layer technique for processing and interpreting massive data set such as collected in continental and global scales studies.

1000000×1000000	7629395	7.629	61.035

Table 1: Comparison between the system memory RAM usage needed to store the full matrix, the BTTB first row and the BCCB eigenvalues (eight times the BTTB). The quantities were computed for different numbers of data (N) with the same corresponding number of equivalent sources (N). This table considers that each element of the matrix is a double-precision number, which requires 8 bytes of storage, except for the BCCB complex eigenvalues, which requires 16 bytes per element.

ACKNOWLEDGMENTS

This study was financed by the brazilian agencies CAPES (in the form of a scholarship), FAPERJ (grant n.º E-26 202.729/2018) and CNPq (grant n.º 308945/2017-4).

LIST OF FIGURES

1 floating points to estimate the parameter vector using the fast equivalent layer with Siqueira et al. (2017) method (equation 19) and our approach (equation 20) versus the numbers of observation points varyig from $N = 5000$ to $N = 1000000$ with 50 iterations. The number of operations is drastically decreased.

2 time necessary to run 50 iterations of the Siqueira et al. (2017) method and the one presented in this work. With the limitation of 16 Gb of memory RAM in our system, we could test only up to 22500 obervation points.

3 time necessary to run the equivalent layer technique with 50 iterations using only this new approach, where the RAM is not a limitation factor. We could run up to 25 million observation points. In comparison, 1 million observation points took 26.8 seconds to run, where the maximun 22500 observation points in figure 2, with Siqueira et al. (2017) method, took 48.3 seconds.

4 model with two polygonal prisms, with density contrast of 0.35 (upper-left body) and $0.4g/cm^3$ (upper-right body), and a sphere with radius of $1000m$ with density contrast of $-0.5g/cm^3$. The vertical component of gravity generated by this bodies were calculated and are shown together with their horizontal projections. A gaussian noise was added to the data with mean of zero and maximum value of 0.5% of the maximum of the original data. As previous said only in regular grids the BTTB matrix structures appears. We created 10000 observation points regularly spaced in a grid of 100×100 , with a uniform $100m$ of height for all the observations.

5 (a) Fitted gravity data produced by the fast equivalent layer proposed by Siqueira et al. (2017). (b) Gravity residuals, defined as the difference between the observed data in Figure 4 and the predicted data in (a), with their mean of $8.264e-7$ and standard deviation

of 0.0144 mGal.

6 (a) Fitted gravity data produced by our modification of the fast equivalent layer proposed by Siqueira et al. (2017). (b) Gravity residuals, defined as the difference between the observed data in Figure 4 and the predicted data in (a), with their mean of $8.264e - 7$ and standard deviation of 0.0144 mGal.

7 Difference between the fitted gravity data produced by Siqueira et al. (2017) method (Figure 5a) and by our modified form of this method that computes the forward modeling using the properties of BTTB and BCCB matrices (equation ??).

8 Difference between the estimated mass distribution within the equivalent layer produced by Siqueira et al. (2017) method (Figure 5a) and by our modified form of this method that computes the forward modeling using the properties of BTTB and BCCB matrices (equation ??).

9 The upward-continued gravity data using: (a) the fast equivalent layer proposed by Siqueira et al. (2017) and (b) our modified form of Siqueira et al. (2017) method by using the properties of BTTB and BCCB matrices (equation ??) to calculate the forward modeling. (c) Residuals, defined as the difference between a and b with their mean of $-5.938e - 18$ and standard deviation of $8.701e - 18$. The total computation times in the Siqueira et al. (2017) method and in our approach are 7.62026 and 0.00834 seconds, respectively.

10 The downward-continued gravity data using: (a) the fast equivalent layer proposed by Siqueira et al. (2017) and (b) our modified form of Siqueira et al. (2017) method by using the properties of BTTB and BCCB matrices (equation ??) to calculate the forward modeling. (c) Residuals, defined as the difference between a and b with their mean of $5.914e - 18$ and standard deviation of $9.014e - 18$. The total computation times in the Siqueira et al. (2017) method and in our approach are 7.59654 and 0.00547 seconds, respectively.
